Numerical data: Polynomial transforms

Send feedback

Sometimes, when the ML practitioner has domain knowledge suggesting that one variable is related to the square, cube, or other power of another variable, it's useful to create a **synthetic feature** from one of the existing numerical **features**.

Consider the following spread of data points, where pink circles represent one class or category (for example, a species of tree) and green triangles another class (or species of tree):

Figure 17. Two classes that can't be separated by a line.

It's not possible to draw a straight line that cleanly separates the two classes, but it *is* possible to draw a curve that does so:

Figure 18. Separating the classes with $y = x^2$.

As discussed in the [Linear regression module](#), a linear model with one feature, x_1 , is described by the linear equation:

$$y = b + w_1 x_1$$

Additional features are handled by the addition of terms $w_2 x_2$, $w_3 x_3$, etc.

Gradient descent finds the **weight** w_1 (or weights w_1 , w_2 , w_3 , in the case of additional features) that minimizes the loss of the model. But the data points shown cannot be separated by a line. What can be done?

It's possible to keep both the linear equation *and* allow nonlinearity by defining a new term, x_2 , that is simply x_1 squared:

$$x_2 = x_1^2$$

This synthetic feature, called a polynomial transform, is treated like any other feature. The previous linear formula becomes:

$$y = b + w_1 x_1 + w_2 x_2$$

This can still be treated like a **linear regression** problem, and the weights determined through gradient descent, as usual, despite containing a hidden squared term, the polynomial transform. Without changing how the linear model trains, the addition of a polynomial transform allows the model to separate the data points using a curve of the form $y = b + w_1 x + w_2 x^2$.

Usually the numerical feature of interest is multiplied by itself, that is, raised to some power. Sometimes an ML practitioner can make an informed guess about the appropriate exponent. For example, many relationships in the physical world are related to squared terms, including acceleration due to gravity, the attenuation of light or sound over distance, and elastic potential energy.

If you transform a feature in a way that changes its scale, you should consider experimenting with normalizing it as well. Normalizing after transforming might make the model perform better. For more information, see [Numerical Data: Normalization](#).

A related concept in **categorical data** is the **feature cross**, which more frequently synthesizes two different features.
